Keywords: Fuzzy Logic, Air Quality, Sensor Validation, Classification Problem, Machine Learning.

Abstract: This work considers different fuzzy classifier models to evaluate the air quality of indoor spaces, providing flexible systems related to the imprecision of metrics and parameters since the modeling process. Air Quality is a relevant topic concerning modern society, and the research on air quality evaluation provides important alternatives for improving global environmental governance. In this paper, we discuss the performances of the five fuzzy classifiers named CHI, FURIA, WF-C, FARC-HD, and SLAVE, applied in the data classification from an open dataset from Germany. Thus, this domain knowledge enables us to model the inherent uncertainties of attributes' problems related to Air Quality and Air Quality Index. The results showed that fuzzy approaches offer a valid alternative for determining and correctly classifying indoor air quality with satisfying accuracy, adding flexible modeling in the air quality analysis.

# **1 INTRODUCTION**

Air Quality has been an ever more important subject for quite some time now. According to the World Health Organization (WHO)<sup>1</sup>, 4.2 million deaths occurred in 2016 (Organization, 2016). And this estimate is increasing, as the sources of pollution only get higher.

Accurate sensors are paramount to properly monitoring air quality, introducing sensor validation as a relevant research area. Due to its inherent failures, the literature presents many methods to detect these problems, ranging from classical to machine learning methods and adding flexibility as fuzzy logic methodologies.

Due to its performance, Machine Learning (Nasser and Pawar, 2015) is quite often considered performing sensor validation and applying ranges from simple methods, such as Logistical Regression (Lee, 2005), to the most used ones, like Neural Networks (Mattern et al., 1998). Fuzzy Logic approaches also offer benefits to this field (Wen et al., 2004), quite useful for its interpretability, which gained substantial importance lately, as knowing the reasons behind a prediction has relevant usefulness in

Seibert, V., Bastos, R., Maia, G., Lucca, G., Santos, H., Yamin, A. and Reiser, R

many circumstances.

Flexible computations provided by the fuzzy logical approach promote uncertainty modeling to solve problems where information is imprecise or vague. Whereas in classical set theory, we have no uncertainty model associated with a given set, in fuzzy set theory this is fully possible. Each element of the universe is associated by a (human/program) specialist to its membership degree, which is given as a real number in the interval [0, 1].

Our paper aims to evaluate the performance of Air Quality classifiers, exploring Fuzzy Logic to model the uncertainty related to Air Quality Indexes. Given a set of compounds that directly impact the Air Quality, we evaluate whether the classifiers can determine the categorical classification of the indoor air environment.

This work is organized as follows: First, it introduces some main concepts regarding the subject matter. In Section 3, the most important related works in the field are discussed based on RSL select projects. Next, Session 4 outlines the methodological strategies used in this project. Session 5 contains the achieved results, providing the studied methods comparison. Finally, the last session shows the conclusions, summarizing the findings of this paper.

## 2 MAIN CONCEPTS

This section reports the main parameters and strategies based on selected Fuzzy Rule Classifiers.

## 2.1 Air Quality Index

Air quality, as its name stands, is the field in charge of studying and measuring the quality of the air and is frequently evaluated through its Air Quality Index (AQI), which is a metric that converts the concentration of components into a standard metric, which tells how poor the air quality in said space is. And, the higher its AQI, the worse the Air Quality. Table 1 depicts these metrics and sums up their characteristics.

Table 1: Air Quality Index Table.

Range	Label
0-50	Good
51-100	Moderate
101-200	Unhealthy Sensitive
201-300	Unhealthy
301-400	Hazardous
401-500	Very Hazardous

The AQI is a piece-wise linear function of the pollutant concentration. At the boundary between AQI categories, resulting in a discontinuous jump of one AQI unit. To convert from concentration to AQI, the equation 1 is used, considering the following parameters:

- I =the (Air Quality) index
- C = the pollutant concentration
- $C_{low}$  = the concentration breakpoint that is  $\leq C$
- $C_{high}$  = the concentration breakpoint that is  $\geq C$
- $I_{low}$  = the index breakpoint related to  $C_{low}$
- $I_{high}$  = the index breakpoint related to  $C_{high}$

$$I = \frac{I_{high} - I_{low}}{C_{high} - C_{low}} (C - C_{low}) + I_{low}$$
(1)

Eq.(1) was firstly defined in (Agency., 2016).

### 2.2 Fuzzy Rule Classification Strategies

Air Quality Sensor Validation was subject to many studies. In the systematic review conducted by (Teh et al., 2020), the first methods considered statistical approaches, such as Principal Component Analysis (PCA) (Wold et al., 1987). More recently, new methodologies have produced other proposals as described in (Samal et al., 2019) and (Kumar et al., 2020). While there are still applications for classical approaches, the most popular methods for sensor validation nowadays are from Machine Learning. In (Wang et al., 2018) and (Wang et al., 2019), the results are described based on Recurrent Neural Networks (RNNs) approaches, while (Chen et al., 2019) offers a deep learning method for Air Quality Index modeling.

This paper integrates the approximate reasoning of fuzzy computations and Machine Learning techniques, promoting an alternative to model Air Quality analysis. This synergic approach offers similar performance to pure ML methods whilst providing uncertainty modeling and the data readability inherent in its approach.

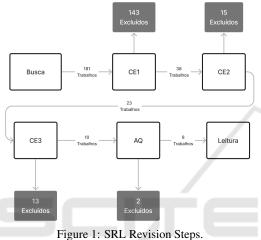

In this paper we have into consideration some of the most well-known Fuzzy Rule-Based Classification Systems (FRBCS), namely:

- CHI. The Fuzzy Rule Learning Model, known as CHI due to its creator (Chi et al., 1996), is a collection of reasoning methods (Cordón et al., 1999), classifying new examples according to the consequence of the rule. And the greatest degree of association is successfully applied to pattern classification problems. In (Ishibuchi and Yamamoto, 2005), to reach further enhancements on CHI, the adoption of heuristics is considered and, the results improve the system performance. So, the work depicts the implications of the distinct vote methods, including the impact of rule weights.
- FURIA. Fuzzy Unordered Rule Induction Algorithm (Hühn and Hüllermeier, 2009) consists of a technique extending the well-known rule learner RIPPER (Cohen, 1995) while preserving its advantages. It learns fuzzy rules instead of conventional rules and unordered rule sets instead of rule lists. Furthermore, it considers an efficient rule-stretching method to deal with uncovered examples.
- WF-C. Proposed in (Nakashima et al., 2007), the Weighted Fuzzy Classifier consists on a method based on if-then rules that allows the incorporation of weighted training patterns, adjusting the sensitivity of the classification with respect to certain classes.
- **SLAVEv0.** The Structural Learning Algorithm in a Vague Environment (Garcia et al., 2014), applying fuzzy-rule learning algorithms, frequently used to benchmark new algorithms.
- FARC-HD. The Fuzzy Association Rule-based Classification (Alcalá-Fdez et al., 2011), a particular approach for high-dimensional problems.

This method considers three stages to obtain an accurate and compact fuzzy rule-based classifier with a low computational cost.

#### 3 **RELATED WORK**

This section briefly discusses the Systematic Review of Literature (SRL) and selection of projects, considering the steps in Figure 1, reporting the exclusion/inclusion criteria and the cut made after the quality assessment.

The first SRL step involves the following Research Question (RQ):

· How do sensory air quality control systems make use of methods based on fuzzy logic and machine learning?

The keywords defined were as follows: Air Quality, Sensors, Machine Learning, and Fuzzy Logic. Based on these keywords, a search string was defined, with the aim of answering the research question:

• "Sensors" AND "Air Quality" AND "Machine Learning" AND "Fuzzy"

The inclusion criterion (IC) considers survey or review articles whose topics are related to Fuzzy Logic or Machine Learning in the context of air quality sensing. Moreover, to remove articles, we considered the following Exclusion Criteria (EC):

- EC1 Reading titles related to the topic.
- EC2 Reading the relevant abstract to the topic.
- EC3 Reading the conclusion of the paper.

The following questions give support to measure the papers quality:

1. Is the work related to air quality sensing?

- 2. Does it use Fuzzy Logic?
- 3. Does it use Machine Learning techniques?
- 4. Is the algorithmical propouses reproducible?
- 5. Is the proposal an open dataset?

Considering a binary answer (yes or no) and a respective associated score (0 or 10) to the average of the answers

The following questions were utilised consider extracting data from the selected works:

- 1. What is the main algorithm used in the work?
- 2. What type of model does this algorithm fit into?
- 3. Where does the work data come from?
- 4. What are the simulation components?

The search in the selected digital libraries, resulted in a total of 181 articles, 8 of which were chosen for full reading, as summarized in Table 2 and described in the following.

Table 2: Papers obtained by Digital Library.

Digital Library	RP	EP
1. Springer Link	111	1
2. ACM Digital Library	23	3
3. Scopus	9	2
4. ScienceDirect	38	2
Total	181	8

RP- Number of returned Papers; 2. EP- Number of Elected Papers.

The selection considered the exclusion/inclusion criteria, evaluating the quality of the articles. After applying EC1, we reduced the number of articles to 38. After EC2, 23 studies remained. EC3 once again reduced the number to 10. Finally, the quality assessment assigned a grade from 0 to 50 for each work, eliminating any with a grade lower than 40 and leaving 08 for the reading stage.

The solution presented in (Alhasa et al., 2018) focuses on low-cost sensors for air quality, considering an adaptive Neuro-Fuzzy inference system. The achievements performed a high rate of linear correlation of the calibration between the applied sensor and the reference instrument. The comparison performance of calibration models as Artificial Neural Fuzzy Inference System (ANFIS) method being the most promising among them.

The research in (Ferreira et al., 2022) proposes an alternative for predicting air quality using a neural network named Fuzzy Adaptive Resonance Theory Map (ARTMAP). The system proved to be a good alternative for predicting air components in indoor environments, making it possible to obtain multiple future predictions using this method.

Article	Algorithm	Algorithm Model Type		Compounds	
1	Linear Regression	Classic	Gas Sensors	CO, CO2, NH3, (CH3)2CO	
2	ANFIS	Neuro Fuzzy	Sensors	PM2.5	
3	ARTMAP	Neuro Fuzzy	Sensors	PM2.5	
4	ANFIS	Neuro Fuzzy	Low Cost Sensors	O3, NO2, CO	
5	Residual GRU	Deep Learning	Open Dataset	O3, NO2, PMs	
6	PANDA	Deep Learning	AQ Station	Weather, AQI, POI	
7	LSTM/GRU	Neural Network	Open Dataset	PM2.5	
8	SARIMA and Prophet	Statistical	Open Dataset	PSO2, NO2, SPM, RSPM	

Table 3: Data Extraction Results from Related Works.

Label Articles: 1: (Kumar et al., 2020); 2: (Bhardwaj and Pruthi, 2020); 3: (Ferreira et al., 2022); 4: (Alhasa et al., 2018); 5: (Wang et al., 2018); 6: (Chen et al., 2019); 7: (Wang et al., 2019); 8: (Samal et al., 2019).

The prediction air quality adopted in (Wang et al., 2018) applies the Deep Multi-task Learning technique. A similar approach in (Chen et al., 2019) considers the context of monitoring urban areas. The first work demonstrates superiority compared to shallow models and nine other *baselines*, while the second shows that an approach using *Gated Recurrent Unit* (GRU) and *Long Short-Term Memomry* (LSTM) is capable of making a reliable prediction for up to 24 hours.

In another approach, in (Bhardwaj and Pruthi, 2020), an adaptive neuro-fuzzy inference system is reported. This case study uses an evolutionary approach to overcome the local optima problem, as Particle Swarm Optimization (PSO) and Genetic Algorithm (GA), optimizing the parameters of the neuro-fuzzy algorithms by ANFIS.

The approach presented by (Wang et al., 2019) considers Recurrent Neural Networks (RNNs) for air quality prediction, promoting a model based on Gated Recurrent Long Short-Term Memory (GRLSTM) by using neural networks doubly recursive methods for prediction. The results show good prediction, although the accuracy is no high.

In the context of time series prediction using the Internet of Things (IoT), we have (Kumar et al., 2020), which makes use of a linear model in conjunction with an array of sensors, enabling to predict the air quality of the next day.

Finally, the results reported in (Samal et al., 2019) consider Seasonal Auto-Regressive Integrated Moving Average (SARIMA) models, as well as Prophet, a predictive model developed by Facebook, to achieve the prediction of air quality time series. Both methods provide a good quality of accuracy, and the best approach is the Prophet model in logarithmic transformation, demonstrating the lowest error metrics.

### 4 METHODOLOGY

The benchmark was conducted through the KEEL<sup>2</sup> Software, which offers a plethora of tools to facilitate the experiments' workflow. The software provides solutions to assess algorithms for data mining problems of various kinds, including regression, classification unsupervised learning, among others, being a tool designed for both research and educational purposes (Alcalá-Fdez et al., 2009).

#### 4.1 Dataset Description

The dataset used in this work belongs to the Aachen University of Applied Sciences, in Germany. It contains over 50 thousand samples, collected in 2023, from March 22 till June 6. The sampling rate used in this dataset was about two minutes, albeit there is some variance between data points  $^3$ .

The dataset contains 31 attributes, 29 ones are statistically described in Table 4. The two attributes that are not in the table are timestamp and measure time, both considering time-related variables and were not used.

The data were classified into a few categories: There is meta information, such as *TypPS*, *tvoc*, *cnt1*, *cnt2.5*, etc., that represents the size or counting of certain particles. Performance and Health are attributes that measure the overall performance and health impact of said sample. Attributes with a "d" prefix indicate a rate of change, such as *dHdt* and *dCO2dt*.

There are a couple of weather-related variables, such as *humidity*, *temperature*, and *pressure*. And, of course, there are measurements for gasses and air particles, such as the *PMs*, *O3*, *NO2*, etc., which are the most important for this research proposal.

<sup>&</sup>lt;sup>2</sup>http://www.keel.es/

<sup>&</sup>lt;sup>3</sup>https://www.kaggle.com/datasets/welfposer/2023indoor-air-quality-dataset-germany

During the exploratory analysis, at  $9^{th}$  July of 2023, we considered the following reported data anomalies:

- (a) Measurement error about fine dust values due to sudden increase in air humidity;
- (b) Lab power outage, probably triggered by a short circuit;
- (c) Large fire in Herzogenrath (9-10km away from measuring location).

From the total of compounds existing in the dataset, there are several different air components, each one of them having specific thresholds to evaluate its impact on air quality. In order to compare them, the WHO limits for O3, NO2, PM10, and PM2.5 were employed to generate labels measuring their Air Quality Index, thus making them comparable.

Table 4: Statistical descriptions for each attribute.

## 4.2 Data Pre-Processing and Transformation Description

Only a subset of these attributes have an actual impact on Air Quality. To be more specific, the WHO defines Air Quality Index limits for *O3*, *NO2*, *PM10* and *PM2.5*, as depicted in Table 5.

Table 5: AQI Limits as defined by WHO.

Linguist variables	pm2.5	pm10	03	no2
Good	10.0	20.4	33.9	21.5
Moderate	25.4	50.4	51.2	106.6
Unhealthy Sens.	37.4	66.4	71.6	177.9
Unhealthy	48.4	83.4	95.6	248.6
Very Unhea.	54.4	91.4	108.9	284.8
Hazardous	60.9	100.9	122.9	319.6
Hazardous	100.0	200.0	255.1	531.9

Furthermore, the dataset was highly unbalanced. Of the six categories of air quality, almost 90% of it lay in the moderate or improved categories. In addition, as one can observe in Figure 2, presenting their distribution and showing how most of the samples lie within the first two classes. As it is, the dataset is impractical for classification models.

To address that, a data augmentation technique was employed: The Synthetic Minority Oversampling Technique (SMOTE) (Chawla et al., 2002), which is considered the standard framework for learning from imbalanced data, due to its simplicity in design and robustness when applied to different types of problems (Fernández et al., 2018).

## 5 MAIN RESULTS

Several experiments were conducted through the KEEL Software(Alcalá-Fdez et al., 2009). The labels were generated using PM1, PM2.5, O3, and NO2, through the piece-wise linear equation 1. Then, to compose the inputs, five attributes were used: temperature, humidity, CO, CO2, and SO2.

After expanding the dataset with SMOTE, 30 thousand examples were achieved, 10 thousand for each class, Thus, the baseline for accuracy would be 33%. The elected three classes are due to a grouping combination, expanding the dataset. Six possible classes were combined, all of them worse than AQI 2. After the data, the SMOTE method was applied, resulting in the final dataset used for the tests.

The methods consider K-Fold cross-validation, as it offers a balance between upward bias and computational requirements (Fushiki, 2011). The crossvalidation applies the standard from the literature, which is tenfold.

See, the parameters of algorithmic approaches: CHI's Parameters:

- T-norm: Product
- Reasoning Method: Winning Rule
- · Penalized Certainty Factor: Rule Weight

WF's Parameters:

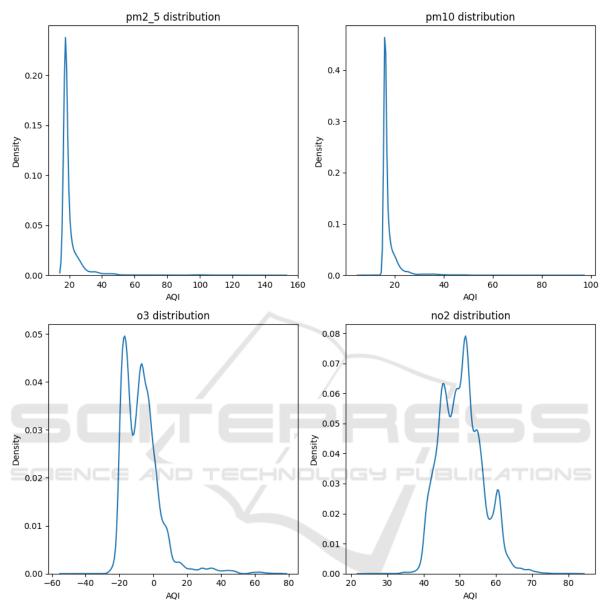

Figure 2: Air Quality Index Distribution per compound.

Table 6: Accuracy of each algorithm.

- Number of Iterations Allowed without Change = 500
- Mutation Probability = 0.5
- Crossover Probability = 0.1
- Lambda = 0.8

The main accuracy results from tests simulated through KEEL are reported in Table 6, containing the accuracy for each fold of the tested algorithms, both for testing and training, with the final row displaying the average for each one. The best train and test results for each row are highlighted in bold.

FURIA far outperformed the other methods, in all case study simulations, with an average accuracy of 0.9991, being the consistently the best method in all folds, both in training and test. The second-best technique was FARC-HD, with an average accuracy of 0.9644. The worst method was CHI, with an average accuracy of 0.9051.

## 6 CONCLUSION

This work analyzes the performance of five different fuzzy-based rule classifiers, such as CHI, WF, FU-RIA, FARCHD, and SLAVE, to compare the distinct classification strategies in measuring air quality based on a set of sensors.

FURIA algorithm proved to be, by far, the best method, outperforming the other approaches with an outstanding 0.9991 average accuracy. The other studied methods didn't fall too far behind, presenting average accuracy values ranging from 0.9 to 0.96, elucidating the performance of fuzzy classifiers.

The results provided by these flexible algorithms showed that fuzzy logic offers a valid alternative for determining the air quality of an environment, modeling the uncertainty related to the subset of the attributes selected by this proposal, correctly classifying the indoor air quality with satisfying accuracy, within an easy to model setup given by the software tool of choice.

As future work, datasets from other places could be used, thus eliminating any bias regarding the location at which the data was collected. Data extension containing other attributes could also be explored, as increasing the number of inputs would assess the scalability of the aforementioned methods.

Furthermore, the ongoing research prospect multivalued fuzzy approaches, such as interval-valued fuzzy algorithms, which should potentially grant a robust solution. In this case, modeling not only the uncertainty referred to the lack of available information but also included imprecision. The more imprecision modeled, the more correct the statements. They may also be due to a multiple-source database air quality system, different vocabularies for expressing attribute values, and different partitions of the same universe of discourse.
